11 **ABSTRACT**

12           One major part of salmon recovery efforts was the introduction of fish passages, such as  
13 fish ladders, to allow salmon to circumnavigate dams and reach historical spawning grounds.  
14 While an increasing number of fish passages allow fish to access historical spawning grounds,  
15 we cannot expect the fish to immediately take full advantage of this increased habitat. It is  
16 unknown how long on average it takes for salmon to fully recolonize the habitat above  
17 passages. One such passage is the Landsburg Fish passage which was put in on the Landsburg  
18 dam on the Cedar river in 2003. I used data taken in Rock Creek, a tributary of the Cedar River,  
19 by the University of Washington to fit growth models to the number of Coho utilizing this newly  
20 accessible habitat. I found that both logistic and geometric growth models fit the data almost  
21 evenly. While Coho numbers varied largely year to year, the reaches I used as an index reached  
22 carrying capacity in five years, likely because of a healthy reproducing population down river of  
23 the dam.

26 Keywords: Salmon, Dam, growth model, logistic growth, geometric growth

27

## 28 INTRODUCTION

29 Salmon have long been an icon of the Pacific Northwest, sustaining native communities and  
30 supporting thriving ecosystems. These iconic fish bring nutrients from the ocean, important for  
31 aquatic and terrestrial ecosystems. These nutrients speed the growth of trees in riparian zones  
32 and support brown bears as they prepare for hibernation and cub production. Salmon carcass  
33 abundance has been correlated to average brown bear litter size, average female brown bear body  
34 mass and eagle nest activity (Hilderbrand et al, 2004). Historically over 130 terrestrial  
35 vertebrates benefitted from nutrients from salmon carcasses (Feddern et al, 2019).

36 As western settlers moved in during the early 19th century, beaver trappers demolished  
37 the beaver population, reducing the amount of ideal salmon habitat, resulting in a decrease from  
38 the salmon population. In the 1930s, massive dams were built as public work projects to employ  
39 those who had lost their jobs during the Great Depression. As the population of the western  
40 United States grew, the demand for energy, land, and water increased drastically, resulting in the  
41 damming of many more river systems to produce hydropower. Salmon paid the price. These  
42 dams blocked salmon migration, preventing them from reaching their spawning grounds. As  
43 salmon could no longer reach suitable habitat to spawn, population numbers in Canada and the  
44 western United States declined to as little as 10% of their historical numbers (Lackey, 2009).

45 As the abundance of salmon continued to decline, our knowledge and understanding of  
46 these fish grew. Many individuals and organizations started to push for recovery efforts. In 1985,  
47 the governments of Canada and the United States ratified the Pacific Salmon Treaty in an effort  
48 to promote research, recovery and understanding of transboundary salmon stocks (Pacific  
49 Salmon Commission). In 2000, the Pacific Coastal Salmon Recovery Fund was established to  
50 reverse the population declines of Pacific salmon in the western United States (NOAA).

51           One major part of salmon recovery efforts was the introduction of fish passages, such as  
52 fish ladders that allow salmon to circumnavigate dams and reach historical spawning grounds.  
53 The National Fish Passage Program (NFPP) is a program funded by the U.S. Fish and Wildlife  
54 Service (USFWS) that partners with federal, state and non-governmental organizations, tribes,  
55 universities and local communities to provide financial and technical assistance for the  
56 reconnection of aquatic habitats (US Fish and Wildlife). This program allows organizations  
57 access to funding to build fish passages as part of their recovery efforts.

58           Since its installation in 1901, the Landsburg Diversion Dam on the Cedar River had  
59 prevented salmon from reaching spawning grounds in many of the river's tributaries. In 2003, a  
60 fish passage was added to the Landsburg Division Dam on the Cedar River in effort to revive  
61 salmon population in the area (Landsburg Fish Passage Facilities). Since its installation in 2003,  
62 NOAA Fisheries, Seattle Public Utilities and scientists from the University of Washington have  
63 been working together to monitor use of the fish passage and collect data to evaluate the  
64 effectiveness of the Landsburg fish passage project (Salmon Recolonization). Additionally,  
65 scientists from the University of Washington have been monitoring the number of Coho salmon  
66 that use the fish passage and reach historical spawning grounds in Rock creek. Looking at this  
67 data can provide an understanding of the effectiveness of these recovery efforts and provide  
68 useful information as to what recovery efforts might still be needed. While these passages allow  
69 fish to access historical spawning grounds, we cannot expect the fish to immediately take full  
70 advantage of this increased habitat. It is unknown how long on average it takes for salmon to  
71 fully recolonize the habitat above passages.

72

73           The goal of this study was to see if basic population growth models could be applied to  
74 smooth variability and capture general trends in Coho population recolonizing new habitat north  
75 of Landsberg dam as a whole. To do this I used three reaches of Rock Creek as an index. I  
76 hypothesize that Coho population will follow a geometric growth pattern.

77

78

79

## 80 **METHODS**

81           Data for this project was provided by the University of Washington School of Aquatic  
82 and Fisheries Sciences. Every year since the input of the fish passage in 2003, members of the  
83 University of Washington have taken electrofishing data at rock creek. Each year, three sites on  
84 Rock creek were sampled, lower, middle and upper rock creek. At each site, two habitats were  
85 sampled, a rifle and a pool. At each habitat site, researchers used a backpack electro-fisher to  
86 record the length and species of each fish found. Measurements of water velocity, depth and  
87 substrate size were also taken.

88           With the data in excel I created a graph to plot the number of salmon counted per year.  
89 To do this I first filtered the data to only include Coho Salmon. I used a pivot table to find the  
90 number of salmon counted in Rock Creek per year, ignoring both site and habitat.

91           After plotting the data, I fit both a logistic (figure 2) and geometric (Figure 3) growth  
92 model. To fit the logistic growth model I used the equation,  $N_t = K / (1 + e^{a - rt})$ , where “K” is the  
93 maximum value, “a” is the constant of integration, “r” is the growth rate, and “t” is the time in  
94 years. To find these parameters I used the solver package in excel to find values for these  
95 parameters that minimize the difference between the predictions and the actual data points. For  
96 this model r was 2.349.

97 For the geometric model I used the equation  $N_t = N_0 * e^{rt}$ , where  $N_0$  is the initial  
98 population, “r” is the growth rate and t is the time in years. I again used the solver package on  
99 excel to find the value 0.174 for the r parameter. In geometric modeling, initial population must  
100 be greater than zero, so this model starts in 2005 with an  $N_0$  of 3. To see which model fit the  
101 data best, I the sum of squares for each data point in each model. I then totaled the sum of square  
102 values for each model. The model with the lowest total sum of squares value fits the data best.

103 It is important to note that both of these population models assume that the population of  
104 a given year is a function of the population of the previous year, however for Coho salmon it  
105 takes juveniles three years to mature to reproducing age meaning the population in a given year  
106 is determined mainly by the population of juveniles three years prior. That said, these models  
107 still give us a good approximation to model salmon population growth.

108  
109

110

## 111 **RESULTS**

112 In this study, the number of Coho salmon captured in Rock Creek varied dramatically  
113 over the years since the fish passage was installed at Landsburg Dam. As predicted, salmon were  
114 more abundant in 2019 than in 2003, but contrary to my prediction, the population did not slowly  
115 increase over time. Instead, the population was highly variable (Figure 1). The first few years of  
116 the data, until around 2009 seem to follow the expected pattern. For the first two years in which  
117 the Rock Creek habitat was available (i.e., 2003 and 2004), no juvenile salmon were detected. In  
118 2005, the first juvenile Coho salmon were observed in Rock Creek habitat since the early 1900s,  
119 when the Landsburg Dam was completed. After that, salmon increased yearly until a sudden  
120 drop in 2009. The catch then quadrupled in 2010 to 28, followed by a two-year period where

121 only four salmon were counted in Rock Creek. This two-year low was followed immediately by  
122 two years of increasing catch, which was followed by another sharp decrease and increase. In  
123 2017, only one juvenile Coho salmon was captured in Rock Creek, the smallest number of  
124 salmon to be caught in Rock Creek since 2004. Surprisingly, this was followed immediately by  
125 an increase where numbers rose from one to 53 between 2017 and 2019.

126 Surprisingly the logistic and geometric growth models were almost equally variable from  
127 the actual data (Figure 2). Ultimately, the logistic growth model fit the data better than the  
128 geometric growth model, although the difference in the total sum of squares was only 34.

129  
130

## 131 **DISCUSSION**

132 When fitting the models, I hypothesized that the geometric growth model would be a  
133 closer fit to the actual data than the logistic model, because this is a newly establishing  
134 population and therefore I did not think it would be affected by density dependent factors which  
135 could cap population growth. Additionally, upon plotting the data, salmon population did  
136 increase as time went on, seeming to follow a pattern of geometric growth and did not seem to  
137 level out, which would indicate carrying capacity and logistic growth. The logistic model  
138 flattened out at a catch of 18 after 5 years, but this leveling out was not seen in the actual catch  
139 data, leading me to believe the geometric model would fit the data better. Contrary to my  
140 hypothesis, when I ran the sum of squares the logistic growth model better fit the data and  
141 captured the general trend of the population as a whole.

142 The most interesting aspect of the logistic model is that it shows the salmon in the three  
143 reaches of Rock Creek, reaching carrying capacity within 5 years. One potential reason for this  
144 speedy recolonization of new habitat could be the healthy population of Coho that spawned

145 below Landsberg Dam before the input of the fish passage. According to the Washington State  
146 Department of Fish and Wildlife, there were 74,507 downstream juvenile Coho salmon  
147 migrations in the Cedar river in 2003, meaning there was a large and healthy population in the  
148 river that were available to recolonize Rock Creek. It is likely that this large source population is  
149 what allowed Rock Creek salmon to reach carrying capacity so quickly (Volkhardt, 2005).  
150 Although while looking at the actual fish catches, it may not seem like the population has  
151 reached carrying capacity, it is normal for populations to increase and decrease around carrying  
152 capacity. These fluctuations can be extremely large in a new population but tend to level out over  
153 time, a process referred to as damping oscillation. The large fluctuations we see in the catch data  
154 are likely because the population is so new, and it is too soon to see the “leveling out”.

155         While the logistic model was closer to the actual data, the closeness of the geometric  
156 model is important. In 2012, similar research was published about salmon recolonization of the  
157 Cedar River, which found the number of natural origin Coho recruits to follow a geometric  
158 pattern (Anderson, 2012). This shows that while the geometric model was slightly less accurate  
159 in this case, it may be far more accurate in other cases.

160         Plotting the data showed many increases and decreases in the numbers of salmon caught  
161 in Rock Creek between 2003 and 2019. While some of the drops and spikes in numbers seem  
162 sudden, especially the drop in 2009, this is not unusual considering environmental stochasticity  
163 has a larger effect on smaller populations. While this variation is normal, it does make it harder  
164 to see general population trends. Although this data seems promising for future salmon  
165 recolonization after barrier removal, salmon’s long-life cycle means it can often take up to 20  
166 years of monitoring to determine the success of recolonization after barrier removal (Weiser,  
167 2008).

168           While these models are by no means perfect because they do not account for the  
169 semelparous life cycle, my results show that they can still be used to “smooth” variability and  
170 understand general population trends. These general models are incredibly easy to make and can  
171 be applied to virtually any recolonization effort, proving their usefulness. Overall, more time is  
172 needed to assess the effectiveness of the Landsburg fish passage and salmon recolonization of  
173 Rock Creek, but these models are promising tools for management.

174  
175

## 176 **ACKNOWLEDGMENTS**

177 I would like to Thank Chelsea Wood and Mark Sorel of the University of Washington for  
178 helping me with this paper. Not only did they provide the data, but they made suggestions  
179 relating to the organization of this paper. Additionally, Mark Sorel taught me how to make the  
180 population growth models. I would also like to thank Jessica Duong for reading over my rough  
181 draft and leaving me helpful suggestions.

240 **Figure captions.**

241

242 List all the figure captions here, with an extra space between them.

243 Fig. 1. Locations of 21 receivers used for within-basin analysis; the size of the circle represents

244 the score of that location on the first principal coordinate. Receivers are numbered in order of

245 decreasing site use (1 = most frequently used, see Table 2), with receivers categorized as

246 deep/offshore in white and shallow/onshore in gray.

247

248 Fig. 2. Caption here

249

250

251 **Fig. 1.**

252

253 Figures should always be in black and white unless the journal is produced on-line only. Such  
254 on-line journals are usually happy to have color but color in print journals is really expensive and  
255 they will charge you for it.

256

257 Avoid putting boxes around figures, and avoid titles or headings within the figure that are  
258 redundant with the captions. Most journals also want you to describe in the caption what the  
259 different symbols (open circles, filled diamonds, etc.) or bar colors (white, black, cross-hatched)  
260 refer to. I think this is stupid but I've lost the battle on many occasions. So, rather than having  
261 information in the figure itself (e.g., black bars = males, white bars = females) you'd say so in  
262 the caption.
